# Sieve of Eratosthenes and Efficient exponentiation 

By Muhammad Khan

## Sieve of Eratosthenes

The sieve of Eratosthenes is an algorithm for finding all prime numbers in the range $[1 ; n]$ in $O(n \log \log n)$ time and requiring only n bits of memory.

The algorithm works as follows:

1. Create a Boolean array of size n and mark each number in the array from 2 to n as prime (by setting the value at each index of the array to true).
2. Set $p$ equal to 2 (the smallest prime number).
3. Mark each multiple of $p$ starting from $p^{2}$ as composite (by setting the value at that index of the array to false).
4. Iterate through the rest of the array. For each prime number set $p$ equal to this number. If $p$ is greater than $\sqrt{n}$ then the algorithm is done. Otherwise repeat step 3 . The next prime number at each point of the algorithm will be the next number in the array that is marked as prime.

## Example

Find all prime numbers from 1 to 40
Create a Boolean array of size n and mark each number in the array from 2 to n as prime

|  | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 |
| 25 | 26 | 27 | 28 | 29 | 30 | 31 | 32 |
| 33 | 34 | 35 | 36 | 37 | 38 | 39 | 40 |

## Example

Find all prime numbers from 1 to 40
Set all proper multiples of 2 (multiples of 2 that are greater than 2 ) as composite

|  | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 |
| 25 | 26 | 27 | 28 | 29 | 30 | 31 | 32 |
| 33 | 34 | 35 | 36 | 37 | 38 | 39 | 40 |

## Example

Find all prime numbers from 1 to 40
The next prime number is 3 so mark all proper multiples of 3 as composite

|  | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 |
| 25 | 26 | 27 | 28 | 29 | 30 | 31 | 32 |
| 33 | 34 | 35 | 36 | 37 | 38 | 39 | 40 |

## Example

Find all prime numbers from 1 to 40
The next prime number is 5 so mark all proper multiples of 5 as composite

|  | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 |
| 25 | 26 | 27 | 28 | 29 | 30 | 31 | 32 |
| 33 | 34 | 35 | 36 | 37 | 38 | 39 | 40 |

## Example

Find all prime numbers from 1 to 40
The next prime number is 7 . However 7 is greater than $\sqrt{40}$ so the algorithm is done. The remaining numbers that are unmarked are
prime numbers.

|  | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 |
| 25 | 26 | 27 | 28 | 29 | 30 | 31 | 32 |
| 33 | 34 | 35 | 36 | 37 | 38 | 39 | 40 |

## Why the algorithm works

$\diamond$ A number is prime if it is not divisible by any prime number smaller than it. Because we iterate through the numbers in order, if we reach a number that has not yet been marked as composite, then this number is a prime number.
$\diamond$ For each prime number $p$, we mark each multiple of $p$ as composite, starting from $p^{2}$. This is because each multiple of $p$ less than $p^{2}$ has a prime factor less than p .
$\diamond$ If the current value of $p$ is greater than $\sqrt{n}$, then the algorithm is done. This is because each composite number in the range [1; n] has a prime factor less than or equal to $\sqrt{n}$.
bool prime[n];
for $\mathrm{i}=2$ to n :
prime[i] $=$ true;
for $\mathrm{i}=2$ to n :
if prime $[i]==$ true:

$$
\mathrm{j}=\mathrm{i}^{*} \mathrm{i} \text {; }
$$

$$
\text { while } \mathrm{j}<=\mathrm{n} \text { : }
$$

prime[j]=false;

$$
j=j+i ;
$$

## Example implementation

```
int n;
bool prime[n+1];
for(int i=2; i<=n; i++)
    prime[i]=true;
for(int i=2; i*i<=n; i++){
    if(prime[i])
        for(int j=i*i; j<=n; j+=i)
            prime[j]=false;
}
```

## Linear sieve

The linear sieve algorithm is an alternative algorithm to the sieve of Eratosthenes. It has a time complexity of $\mathrm{O}(n)$. However, the downside is that it requires $n$ bytes of memory whereas the sieve of Eratosthenes only requires $n$ bits.

An advantage of using the linear sieve is that we can easily calculate the prime factorisation of any number in the range $[2 ; n]$ after all the preprocessing is done.

## How the algorithm works

We create an array $l p$ which will contain the minimum prime factor of each number $i$ in the range [ $2 ; \mathrm{n}]$. Initially, this array will contain zeroes at every index, indicating that these numbers are all prime.

Each time we encounter a prime number, we store this number in an array pr .

We then traverse through the array. At each index $i$ we have two possibilities:
If $l p[i]=0$ then $i$ is a prime number.
If $l p[i] \neq 0$ then $i$ is a composite number and its minimum prime factor is $l p[i]$.

We then update numbers in the array that are divisible by $i$ in a way that each number is only updated once.

## Example implementation

```
std::vector<int> lp(n+1), pr;
for(int i=2; i <= n; i++){
    if(lp[i]==0){
        lp[i]=i;
        pr.push_back(i);
    }
    for(int j=0; i * pr[j]<=n; j++){
        lp[i* pr[j]] = pr[j];
        if(pr[j]==lp[i])
            break;
    }
}
```

## Why the algorithm works

Each number $i$ has a unique representation in the form $i=l p[i] \cdot x$ where $l p[i]$ is the minimum prime factor of $i$ and the number $x$ doesn't have any prime factors less than $l p[i]$.
Our algorithm therefore goes through each prime number multiple $p$ of $i$, and sets the lowest prime factor of this number to be $p$ while $p \leq l p[x]$.

## Binary exponentiation

Binary exponentiation is a method of calculating $a^{n}$ using $O(\log n)$ multiplications.
By expressing $n$ in its base 2 representation, we can calculate $a^{n}$ by doing at $\operatorname{most}^{\log _{2} n}$ multiplications. For example, $5^{11}=5^{1011_{2}}=5^{8} \cdot 5^{2} \cdot 5^{1}$

We can therefore calculate $a^{n}$ efficiently if we know $a^{1}, a^{2}, a^{4}, \ldots, a^{\left[\log _{2} n\right\rfloor}$. These numbers can be found by starting with $a$ and repeatedly squaring it. We can then use bitwise operations to determine if the current power of $a$ should be included in the representation of $a^{n}$.

The algorithm can be extended to calculate $a^{n} \bmod m$.

## Example C++ implementation

```
long long binary(long long a, long long n){
    long long answer=1;
    while(n>0){
        if(n&1)
            answer*=a;
        a*=a;
        n>>=1;
    }
    return answer;
}
```

## Example C++ implementation using mod

```
long long binary(long long a, long long n, long long m){
    a%=m;
    long long answer=1;
    while(n>0){
        if(n&1)
            answer=answer*a%m;
        a*=a;
        n>>=1;
    }
    return answer;
}
```

## Practice problem

Given two integers $a$ and $b$, find the last digit of $a^{b}$.

Input
Two integers, $a(0 \leq a \leq 20)$ and $b\left(0 \leq b \leq 10^{10}\right)$

Output
One integer, d , the last digit of $a^{b}$.

## Answer

Calculate $a^{b} \bmod 10$ using binary exponentiation
